ABSTRACT

A variety of arguments strongly suggest that the density of the universe is no more than a tenth of the value required for closure. Loopholes in this reasoning may exist, but if so, they are primordial and invisible, or perhaps just black.

Subject heading: cosmology

Desist from thrusting out reasoning from your mind because of its disconcerting novelty. Weigh it, rather, with a discerning judgment. Then, if it seems to you true, give in. If it is false, gird yourself to oppose it. For the mind wants to discover by reasoning what exists in the infinity of space that lies out there, beyond the ramparts of this world. . . . Here, then, is my first point. In all dimensions alike, on this side or that, upward or downward through the universe, there is no end.

Star Formation Unbound

At what scales does gravity truly play the key role in the story of star formation?

Star Formation Unbound

A Modest Suggestion

- **Suppose molecular clouds are not bound**
 - **Just part of the mostly atomic flow that becomes molecular for a while**
 - **Collisions, turbulence causes a small fraction (few percent) to become bound dense clumps**
 - **The rest of the molecular gas rejoins the atomic flow**
 - **Galactic feedback keeps ISM stirred up, unbound**

"[I will now propose heresy...] Suppose molecular clouds are not bound."

ABSTRACT

After studying how line width depends on spatial scale in low-mass star-forming regions, we propose that “dense cores” (Myers & Benson 1983) represent an inner scale of a self-similar process that characterizes larger scale molecular clouds.

FIG. 10.—An illustration of the transition to coherence. Color and shading schematically represent velocity and density in this figure. On large scales, material (labeled chaff) is distributed in a self-similar fashion, and its filling factor is low. On scales smaller than some fiducial radius, the filling factor of gas increases substantially, and a coherent dense core, which is not self-similar, is formed. Due to limitations in the authors’ drawing ability, the figure emphasizes a particular size scale in the chaff, which should actually exhibit self-similar structure on all scales ranging from the size of an entire molecular cloud complex down to a coherent core.

The story I want to think about today...

Abstract: Urban expansion has become a widespread trend in developing countries. Road networks are an extremely important factor driving the expansion of urban land and require further study. To investigate the relationship between road networks and urban expansion, we selected Beijing, New York, London, and Chicago as study areas. First, we obtained urban land use vector data through image interpretation using a remote sensing (RS) and geographic information systems (GIS) platform and then used overlay analysis to extract information on urban expansion. A road network density map was generated using the density analysis tool. Finally, we conducted a spatial statistical analysis between road networks and urban expansion and then systematically analyzed their distribution features. In addition, the Urban Expansion-Road Network Density Model was established based on regression analysis. The results indicate that (1) the road network density thresholds of Beijing, New York, London, and Chicago are 18.9 km/km², 37.8 km/km², 57.0 km/km², and 64.7 km/km², respectively, and urban expansion has an inverted U-curve relationship with road networks when the road network density does not exceed the threshold; (2) the calculated turning points for urban expansion indicate that urban expansion initially accelerates with increasing road network density but then decreases after the turning point is reached; and (3) when the road density exceeds the threshold, urban areas cease to expand. The correlation between urban expansion and road network features provides an important reference for the future development of global cities. Understanding road network density offers some predictive capabilities for urban land expansion, facilitates the avoidance of irregular expansion, and provides new ideas for addressing the inefficient utilization of land.

edge-on

Dear Alyssa,

guide & caveats, from Andi Burkert

here is a simulation of the formation of the Nessi filament. The line-of-sight is the x-coordinate. So we see Nessie in the y-z plane.

We impose a gravitational potential well in the y-direction, located at $x=0=z$. Gas enters the potential well from the negative x-axis and then gets trapped and generated the filament. White dots show the stars forming in the filament. Feedback is included. At some point the filament mass becomes so massive that it collapses onto itself and forms a dense star cluster. **In reality tidal shear would prevent that from happening.**

The 3 movies show the gas and stars in x-y, x-z and y-z projection. As the movies are too large to send via email, here is a link where you can download them:

doi:10.1038/nature14166

The formation of a quadruple star system with wide separation

Jaime E. Pineda¹, Stella S. R. Offner^{2,3}, Richard J. Parker⁴, Héctor G. Arce⁵, Alyssa A. Goodman⁶, Paola Caselli⁷, Gary A. Fuller⁸, Tyler L. Bourke^{9,10} & Stuart A. Corder^{11,12}

The initial multiplicity of stellar systems is highly uncertain. A number of mechanisms have been proposed to explain the origin of binary and multiple star systems, including core fragmentation, disk fragmentation and stellar capture^{1–3}. Observations show that protostellar and pre-main-sequence multiplicity is higher than the multiplicity found in field stars^{4–7}, which suggests that dynamical interactions occur early, splitting up multiple systems and modifying the initial stellar separations^{8,9}. Without direct, high-resolution observations of forming systems, however, it is difficult to determine the true initial multiplicity and the dominant binary formation mechanism. Here we report observations of a wide-separation (greater than 1,000 astronomical units) quadruple system composed of a young protostar and three gravitationally bound dense gas condensations. These condensations are the result of fragmentation of dense gas filaments, and each condensation is expected to form a star on a time-scale of 40,000 years. We determine that the closest pair will form a bound binary, while the quadruple stellar system itself is bound but unstable on timescales of 500,000 years (comparable to the lifetime of the embedded protostellar phase¹⁰). These observations suggest that filament fragmentation on length scales of about 5,000 astronomical units offers a viable pathway to the formation of multiple systems.

Detailed knowledge of the underlying distribution of dense gas is the key to determining which structures will go on to form stars. Here we identify the dense gas structures that are most likely to form stars using the dendrogram technique²¹. Dendrogram analysis is a hierarchical structure decomposition that uses isocontours to identify individual features, while also determining where these contours merge with adjacent structures to create a new parental structure. We refer to the smallest scale (and brightest) structures in the dendrogram as condensations. These are the most likely places for an individual star to form. Figure 1a shows the B5 region as seen in dense gas (number density of H_2 , $n_{\text{H}_2} \gtrsim 10^4 \text{ cm}^{-3}$), with the protostar and the identified gas condensations shown by a star and circles, respectively. The mass of the well known protostar B5-IRS1 is 0.1 solar masses (M_{Sun} ; ref. 22), while the masses of condensations B5-Cond1, B5-Cond2 and B5-Cond3 are $0.36 \pm 0.09 M_{\text{Sun}}$, $0.26 \pm 0.12 M_{\text{Sun}}$ and $0.30 \pm 0.13 M_{\text{Sun}}$, respectively. Uncertainty in these masses is dominated by the uncertainty in the temperature used to convert measured fluxes to masses. The radii of the three condensations are respectively 2,800 AU, 2,300 AU and 2,500 AU, while the projected separations between the same three condensations and the protostar are 3,300 AU, 5,100 AU and 11,400 AU (see Methods). The half-mass radii of the condensations are about half the condensation radii. This, combined with

Abstract

We present a new technique to determine distances to major star-forming regions across the Perseus Molecular Cloud, using a combination of stellar photometry, astrometric data, and ¹²CO spectral-line maps. Incorporating the Gaia DR2 parallax measurements when available, we start by inferring the distance and reddening to stars from their Pan-STARRS1 and 2MASS photometry, based on a technique presented in Green et al. (2014, 2015) and implemented in their 3D “Bayestar” dust map of three-quarters of the sky. We then refine the Green et al. technique by using the velocity slices of a CO spectral cube as dust templates and modeling the cumulative distribution of dust along the line of sight towards these stars as a linear combination of the emission in the slices. Using a nested sampling algorithm, we fit these per-star distance-reddening measurements to find the distances to the CO velocity slices towards each star-forming region. This results in distance estimates explicitly tied to the velocity structure of the molecular gas. We determine distances to the B5, IC348, B1, NGC1333, L1448, and L1451 star-forming regions and find that individual clouds are located between $\approx 275 - 300$ pc, with typical combined uncertainties of $\approx 5\%$. We find that the velocity gradient across Perseus corresponds to a distance gradient of about 25 pc, with the eastern portion of the cloud farther away than the western portion. We determine an average distance to the complex of 294 ± 17 pc, about 60 pc higher than the distance derived to the western portion of the cloud using parallel measurements of water masers associated with young stellar objects. The method we present
